Case report

A 20-year-old man presented to the emergency department of a district general hospital early in the morning with substernal burning chest pain radiating to the scapulae. The symptoms started two days before during the night and subsided spontaneously. Dyspnea, and an increase of pain on inspiration or on change of position were denied. The patient reported having initiated antibiotic therapy himself as he had suffered from a cold with a sore throat and pyrexia of 39 degrees Celsius a week before the chest pain had started. At presentation, he was in a reduced general state of health. Vital signs were as follows: blood pressure

143/107 mm Hg, heart-rate 65/min, temperature 36.5 degrees Celsius and arterial oxygen saturation 100% on ambient air. The physical examination was unremarkable, and no murmurs or pericardial friction rub were noted. The initial blood results showed a slight elevation of the inflammation values and a significant increase of the cardiac biomarkers (Troponin I 10.12 µg/l [<0.1 µg/l], CK-MB 25 µg/l [<5 µg/l]). The electrocardiogram demonstrated sinus rhythm and slight ST-elevations in the infero-lateral leads. To exclude an acute coronary syndrome, the patient was immediately referred to the university hospital for an urgent coronary angiogram. This demonstrated normal coronary arteries (fig. 1).

The history, clinical presentation and findings were consistent with acute peri-myocarditis, which was most likely post-viral. Cardiac magnetic resonance imaging performed the same day further supported the diagnosis. Global systolic left ventricular function was normal with hypokinesia in basal to midventricular infero-lateral segments with a small pericardial effusion in the area of the basal infero-lateral wall. On T2-weighted and late gadolinium enhancement images, the signal intensity was increased in the basal lateral wall, predominantly in the epicardial layer, suggesting local oedema (fig. 2).

A relief of symptoms was achieved with NSAR and continued antibiotic therapy. We advised the patient to abstain from vigorous exercise for the next three months.

At follow-up three months later, the patient was free from any discomfort. His physical examination, blood results, resting ECG and echocardiography were completely normal.

Discussion

Peri-myocarditis is a focal or diffuse inflammation of variable degree of the pericardium and myocardium and is usually caused in developed countries by viral

infections. Younger individuals (median age 42 years) with a predisposing genetic background are typically affected [1, 2]. Our young patient also reported symptoms of a viral infection.

Damage is caused by direct viral cytolytic or cytotoxic effects with release of intracellular proteins, which mobilise inflammatory cells to the infected foci. This leads to tissue oedema and later to fibrosis. The classical symptom is position-dependant chest pain relieved by sitting forward and worsened by lying down. Infrequently, heart failure and arrhythmias occur which may even lead to sudden cardiac death. Exercise increases the risk of fatal arrhythmias and hence abstinence from sport or other vigorous exercise is recommended for 3 to 6 months [3, 4]. In many cases the clinical course is asymptomatic with the consequence that the syndrome is underreported. As in our patient, the clinical course usually results in a complete recovery without left ventricular impairment but in some cases a reduced function of variable degree persists.

Due to the high spatial resolution and the unique ability to visualise myocardial and pericardial oedema and fibrosis, cardiac magnetic resonance imaging is the ideal imaging modality to assess patients with suspected peri-myocarditis. Differentiation between coronary heart disease and peri-myocarditis is possible.

Late gadolinium enhancement is the most powerful approach to assess myocarditis, however, other imaging techniques like T2-weighted imaging for example in combination with late gadolinium enhancement may even improve the diagnostic performance [5]. In peri-myocarditis, findings include the presence of mainly epicardial and mid-wall late gadolinium enhancement, and an increased focal T2-signal representing myocardial oedema. If visual analysis is inconclusive, quantitative analysis may be helpful since an increased T2 signal ratio between the myocardium and the skeletal muscle may indicate myocarditis [6, 7]. Late gadolinium enhancement in myocarditis can be distinguished from ischemic genesis as it is typically localised in the epicardium extending into the mid-myocardium whereas in ischemic heart disease the endocardium is always affected with variable extension into the mid-myocardium and epicardium and corresponds to a coronary artery territory [8, 9]. Furthermore, in myocarditis the

Figure 2 Short-axis cine image at end-systole demonstrates hypokinesia of the infero-lateral left ventricle (LV) wall (A; white arrows). T2-weighted image (B) shows oedema of the lateral LV wall (white arrows) with corresponding late enhancement infero-lateral in the short-axis (C) and three chamber view (D; white arrows).

most common location for lesions is the lateral wall [10].

As in our patient, the indication for performing cardiac magnetic resonance imaging in acute peri-myocarditis is, in most cases, the affirmation of the suspected diagnosis after exclusion of coronary heart disease by coronary angiogram. Furthermore in patients with potential acute ST elevation myocardial infarction, a time loss by performing cardiac magnetic resonance imaging first is unacceptable [11]. In patients with low pre-test probability regarding coronary artery disease and typical symptoms of peri-myocarditis as in our case, it would be reasonable to omit the coronary angiogram and to provide the diagnosis and extent of myocardial involvement by cardiac magnetic resonance imaging [12].

In addition, cardiac magnetic resonance imaging can be used to guide myocardial biopsy [9, 10]. Endomyocardial biopsy is the gold standard to definitely diagnose myocarditis. However, it is invasive and complications may occur. Therefore, it is only recommended in patients with acute dilated cardiomyopathy associated with haemodynamic compromise and in those with life-threatening arrhythmias. This is to establish the diagnosis and prognosis and to guide therapy [13]. As a result of the focal manifestation of myocarditis, there is a high sample error and the sensitivity of endomyocardial biopsy is low [14]. Cardiac magnetic resonance imaging can be used to obtain samples from the affected regions which allows significant improvement in the sensitivity of myocardial biopsy [10, 15].
